

What's the AVERAGE distance?

$$\begin{aligned}\langle r \rangle &= \int_0^{\infty} r P_{10}(r) dr \\ &= \frac{4}{a_0^3} \int_0^{\infty} r^3 e^{-2r/a_0} dr\end{aligned}$$

like a class of integrals:

$$\int_0^{\infty} z^n e^{-z} dz = n!$$

change variables: $z = 2r/a_0$

$$\langle r \rangle = \frac{a_0}{4} (3!)$$

$$\langle r \rangle = \frac{3}{2} a_0$$

Where is the electron? can't ask that, as you know.

The likelihood of finding the electron between some $r=a$ and $r=b$ will be

$$P_{10}(ab) = \int_a^b P_{10}(r) dr$$

So... what's the likelihood that the electron spends time OUTSIDE of the Bohr orbit?

(still the 1s state of Hydrogen)

$$\begin{aligned} P(r > a_0) &= \int_{a_0}^{\infty} P_{10}(r) dr \\ &= \frac{4}{a_0^3} \int_{a_0}^{\infty} r^2 e^{-2r/a_0} dr \end{aligned}$$

Another class of integrals.

$$\int z^2 e^{-z} dz = -\frac{1}{2}(z^2 + 2z + 2)e^{-z}$$

let $z = 2r/a_0$ again

$$P(r > a_0) = \frac{1}{2} \int_2^{\infty} z^2 e^{-z} dz = 5e^{-2} \sim 0.68$$

$\sim 2/3$ of the time the electron wanders beyond one Bohr orbit.

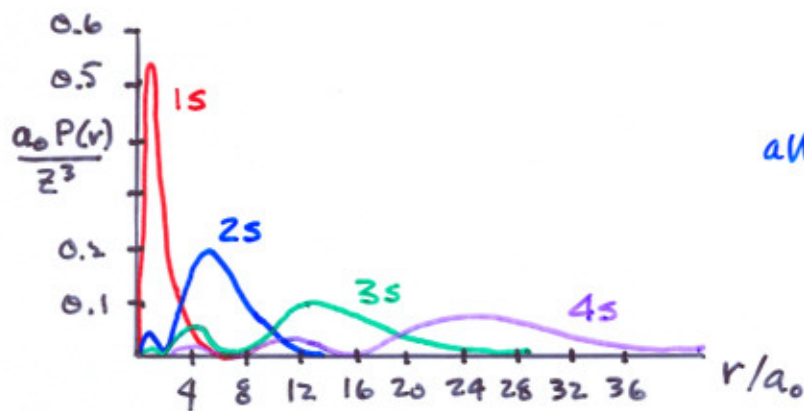

Excited states...

say 2s

Again Y_{00} is relevant, so again, spherically symmetric probability distribution

$$R_{20}(r) = \frac{1}{\sqrt{(2a_0)^3}} \left(2 - \frac{r}{a_0}\right) e^{-r/a_0} \quad (\text{hydrogen})$$

strong density peaks

all spherically symmetric

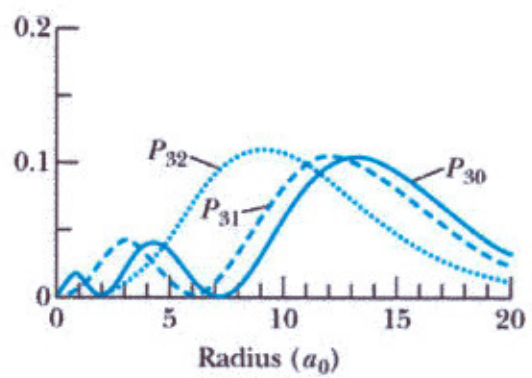

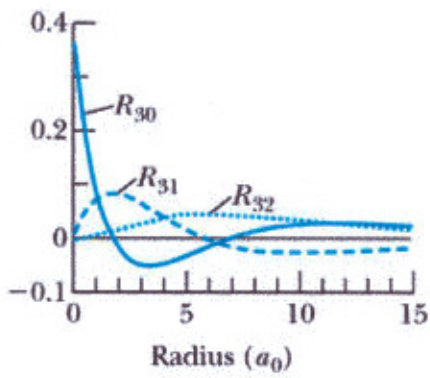

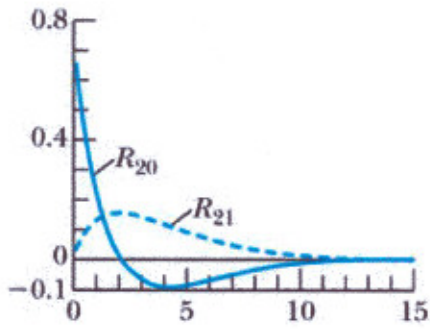

notice that at any radius -- especially around $1a_0$, there is a non-negligible probability of electrons from excited states being where the $1s$ electrons might likely be

But -- obviously, the higher the principle quantum number, the farther away from the nucleus is the most likely.

Radial wave functions (R_{nl})

Radial probability distribution (P_{nl})

Energy.

Remember, E depends only on n .

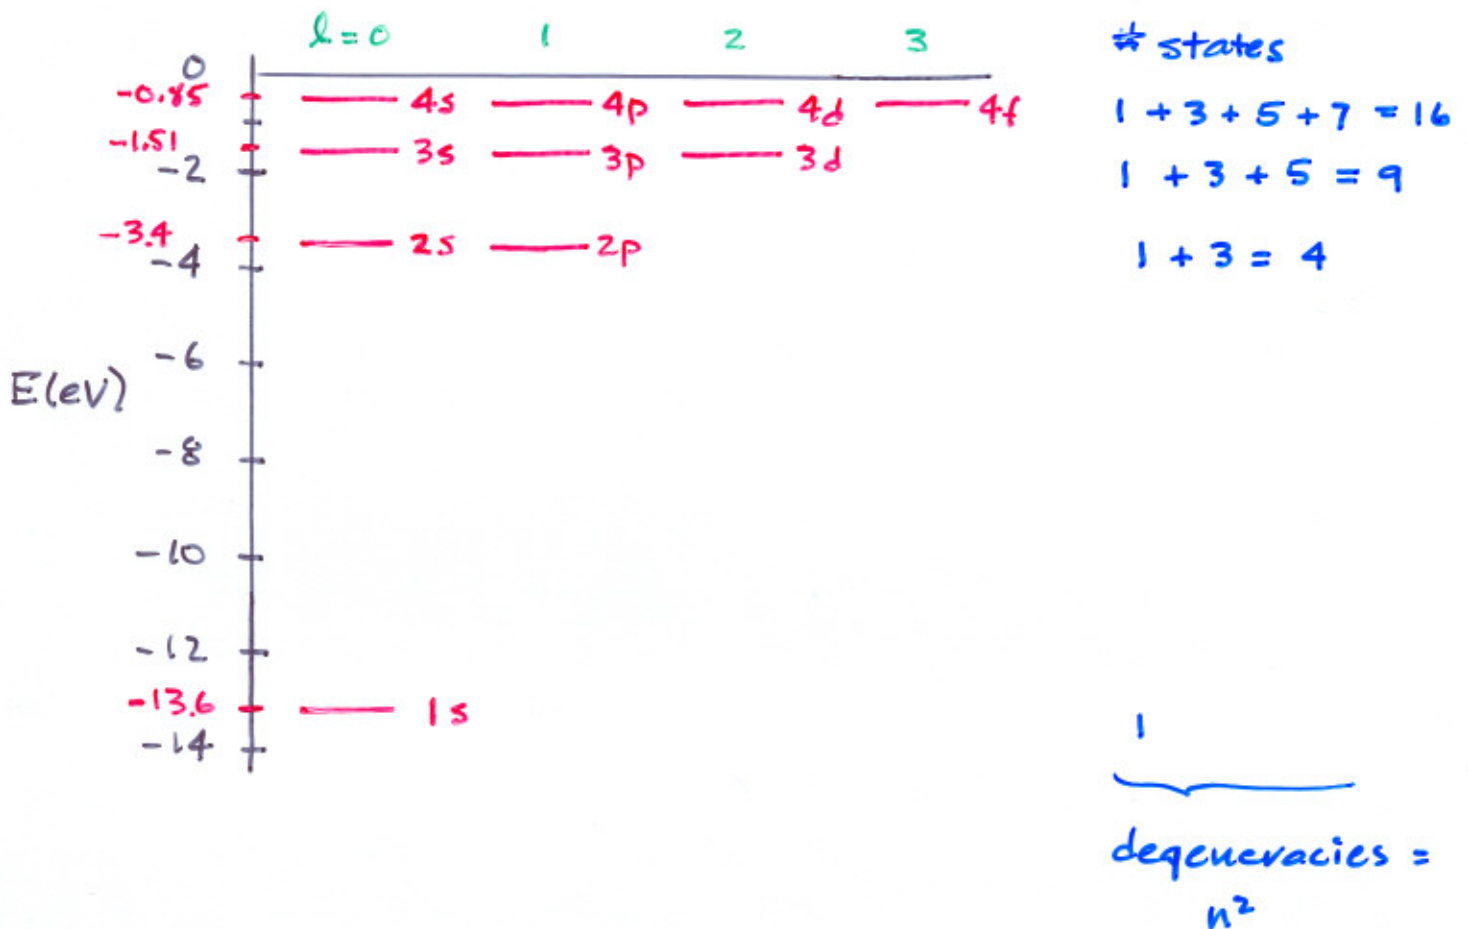

$$E_n = -\frac{E_0}{n^2}$$

$$E_0 = \frac{\hbar^2}{2Ma_0^2}$$

But, each n can result in many values of l .

↳ and m_l

→ substantial Degeneracy in Hydrogen

Figure 7-7 Photographic representation of the electron probability density distribution for various energy eigenstates. These may be regarded as sectional views of the distributions obtained by integrating the probability density over the angular coordinates, retaining the polar axis, which is vertical and in the plane of the paper. The scale varies from left to right. (From *Principles of Modern Physics* by R. B. Leighton. Copyright 1959 by McGraw-Hill Book Company. Used with permission of McGraw-Hill Book Company.)

Since the energy levels are independent of the quantum numbers ℓ and m , we express the degeneracy of each level by the sum

$$\sum_{\ell=0}^{n-1} (2\ell + 1) = 1 + 3 + 5 + \cdots + 2n - 1 = n^2.$$

The $(2\ell + 1)$ -fold degeneracy of the m -values is characteristic of all spherically symmetric potentials, while the n -fold degeneracy of the ℓ -values occurs only for a potential such as the Coulomb potential, which satisfies a specific invariance property.⁵ Historical usage has coined the unfortunate phrase "accidental degeneracy" to describe the latter. The reader can anticipate some of the results of later sections by speculating that any alteration of the physical conditions which destroys the spherical symmetry or the pure Coulombic potential will lead to the removal of some or all of the degeneracies.

Figure 7-7 Continued.

The total hydrogenic wave functions can now be written as

$$\Psi_{n\ell m}(r, \theta, \phi, t) = \psi_{n\ell m}(r, \theta, \phi) \cdot e^{-iE_n t/\hbar} = R_{n\ell}(r) Y_{\ell}^m(\eta, \phi) e^{-iE_n t/\hbar},$$

where n can be any integer, ℓ can take on the values $0, 1, 2, \dots, (n - 1)$, and m can have any of the values $\ell, \ell - 1, \dots, 0, -1, \dots, -\ell$. Although the radial and angular functions have been given above, a few of the normalized spatial, hydrogenic wave functions are tabulated below to facilitate their use in the problems:

$$\psi_{1s} = \psi_{100} = \frac{1}{\sqrt{\pi}} \left(\frac{Z}{a_0} \right)^{3/2} \cdot e^{-Zr/a_0}$$

$$\psi_{2s} = \psi_{200} = \frac{1}{4\sqrt{2\pi}} \left(\frac{Z}{a_0} \right)^{3/2} \cdot \left(2 - \frac{Zr}{a_0} \right) \cdot e^{-Zr/2a_0}$$

$$\psi_{2p} = \psi_{210} = \frac{1}{4\sqrt{2\pi}} \left(\frac{Z}{a_0} \right)^{3/2} \cdot \frac{Zr}{a_0} \cdot e^{-Zr/2a_0} \cos \theta$$

Orbiting electrons should actually show magnetic phenomena.

Recall classical $E \propto M \dots$

a current loop gives rise to a **Magnetic Moment**

$$|\mu| = IA \quad (\text{RH rule gives direction})$$

Suppose it's a charge going in a circle...

$$I = \frac{dq}{dt} \rightarrow \frac{q}{T}$$

↑
period.

If a circular orbit...

angular momentum $L = mvr$

$$v = \frac{2\pi r}{T} \quad A = \pi r^2$$

$$L = m \left(\frac{2\pi r}{T} \right) r = 2m \frac{\pi r^2}{T}$$

$$L = 2m \left(\frac{A}{T} \right) \quad (\text{Kepler's Law})$$

$$\Rightarrow \frac{A}{T} = \frac{L}{2m}$$

So,

$$\mu = IA = \frac{q}{T} A = \frac{q}{2m} L$$

or

$$\vec{\mu} = \frac{q}{2m} \vec{L}$$

if an electron:

$$\vec{\mu} = -\frac{e}{2m} \vec{L}$$

What about atomic electrons.

Thinking in some strange superposition of classical & quantum mechanical ways (!)...

we just found that some orbits - levels - in Hydrogen have specific angular momenta.

$$L = \hbar \sqrt{l(l+1)}$$

which is a vector, but which has a quantized projection onto one axis... we define as z - of

$$L_z = m_l \hbar$$

But... what's the z direction?

NO DIRECTIONS ARE PREFERRED

- symmetrical, so the \vec{L} 's point randomly

unless

something BREAKS that symmetry

and "picks out" or establishes a PARTICULAR direction in space as special.

An external magnetic field does that!

Now those angular momenta...

and through

$$\mu = -\frac{e}{2m} L$$

The atomic magnetic moments... come alive.

$$\mu_z = -\frac{e}{2m} L_z = -\frac{e\hbar}{2m} m_l$$

$$\mu_z = -\frac{e}{2m} \hbar m_l$$

This encompasses a famous quantity ..

"Bohr magneton"

$$\mu_B = \frac{e\hbar}{2m} = 9.274 \times 10^{-24} \text{ J/T}$$

$$\mu_z = -\mu_B m_l$$

So, atomic magnetic moments can be thought of as multiples of μ_B .

REMEMBER E & M:

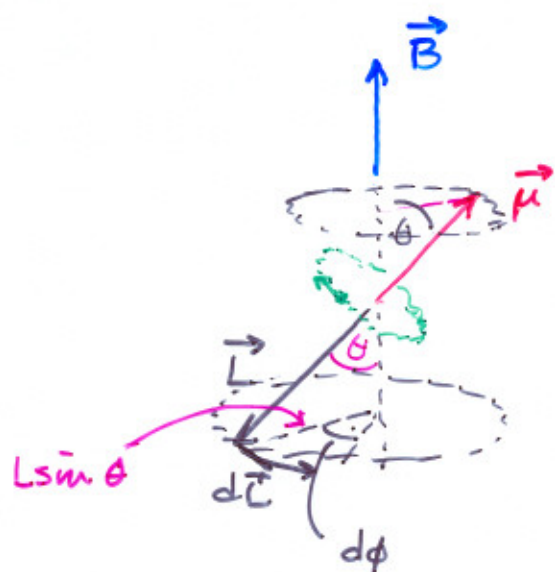

$$\vec{\tau} = \vec{\mu} \times \vec{B}$$

a torque is applied to
a magnetic moment by \vec{B} .
trying to align the moment
and \vec{B}

But, it doesn't align... it precesses... $\mu \propto L$

$$\vec{\tau} = \frac{d\vec{L}}{dt} = \cancel{\mu_B \vec{L} \times \vec{B}} = \frac{q}{2m} \vec{L} \times \vec{B}$$

change in $\vec{L} \perp \vec{L}$ and \vec{B}

$d\vec{L} \perp$ plane of \vec{B} and \vec{L}
 \Rightarrow around the circle

$$|dL| = L \sin \theta d\phi$$

$$d\phi = \frac{|dL|}{L \sin \theta}$$

$$\frac{|dL|}{dt} = \tau$$

$$d\phi = \frac{|\tau| dt}{L \sin \theta}$$

$$d\phi = \frac{q/2m (LB \sin \theta) dt}{L \sin \theta} = \frac{Bq}{2m} dt$$

precession frequency -- called Larmor frequency, ω_L

$$\omega_L = \frac{d\phi}{dt} = \frac{qB}{2m}$$

Since there is a torque through an angular displacement... work is done

$$dW = \tau d\theta$$

$$dW = -\mu B \sin\theta d\theta$$

$$= d(\mu B \cos\theta)$$

$$dW = d(\vec{\mu} \cdot \vec{B})$$

(external torque opposes that of B)

The work done -- is stored as a potential energy

$$dW = -dV$$

So... there is an induced magnetic potential energy:

$$V = -\vec{\mu} \cdot \vec{B}$$

- depends on the external B
- the more aligned... the less is V

BUT... μ is quantized according to L_z

for $l=1$ for example

SO, THE MAGNETIC POTENTIAL ENERGY IS QUANTIZED!

So, if we DEFINE the z direction to be along \vec{B} ...

$$V = \frac{e}{2m} \vec{L} \cdot \vec{B} = \frac{e|B|}{2m} L_z$$

$$V = \mu_B m_l B$$

↖ can range over values $-l$ to $+l$

So, when a magnetic field is applied -- the energy levels change

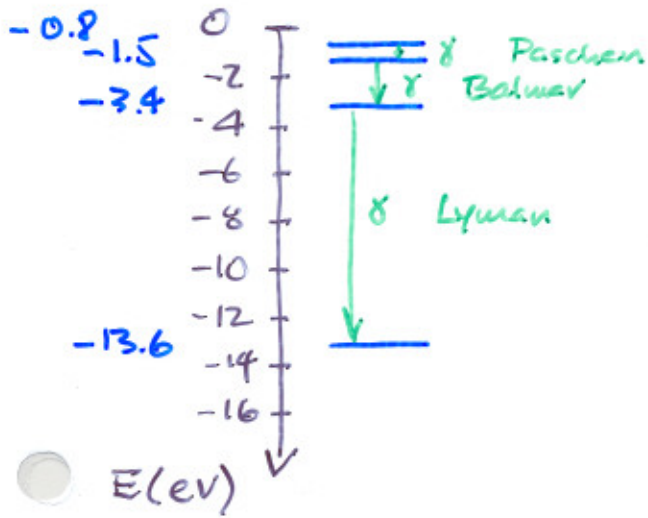

→ that's what Lorentz predicted and Zeeman found.

But, the Schrodinger approach changed even the $B=0$ situation.

$$B=0$$

Remember the Bohr atom & spectra:

BOHR

$n=4$
 $n=3$
 $n=2$

 $n=1$

SCHRÖDINGER

Something comes out of Schrödinger's theory:

- RESTRICTIONS on allowed transitions
- PROBABILITIES -- intensities of emitted light.

* Selection Rule *

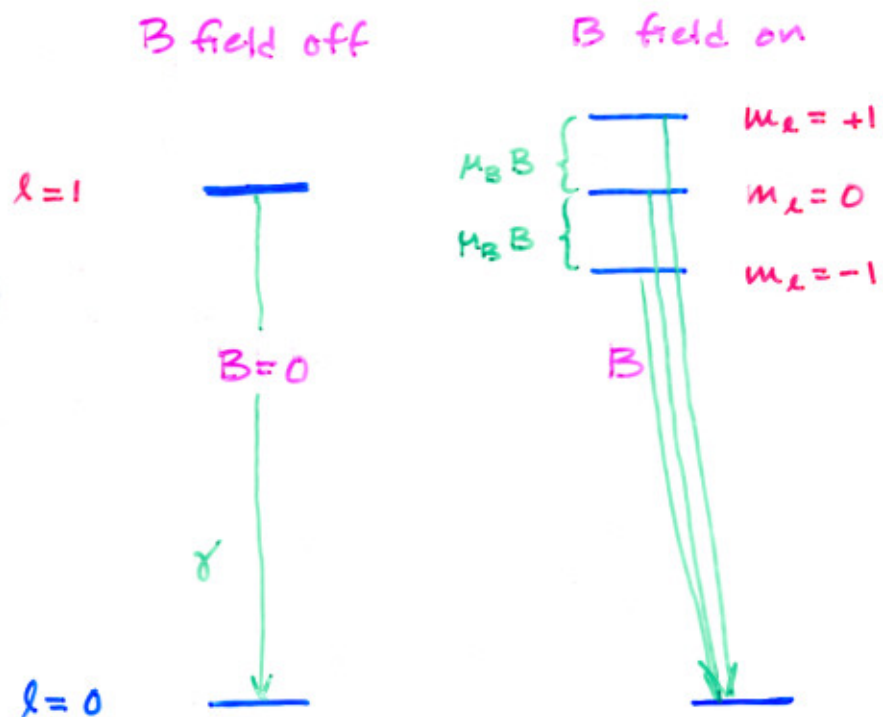

$$\Delta l = \pm 1$$

for γ emission

like: $2p \rightarrow 1s$ OKAY
 $2s \rightarrow 1s$ forbidden

What about a magnetic field?

The potential associated with $\vec{\mu} \cdot \vec{B}$ is added to the energy of the state with $B=0$

* Selection Rule *

$$\Delta m_l = 0, \pm 1$$

Region outside of sunspot

B

This splitting into 3 is called the
Normal Zeeman Effect

You guessed it... there's such a thing as the
Anomalous Zeeman Effect

There's a history here...

Known from the beginning... the Anomalous Z.E.
had no classical features ("normal" meant that
Lorentz could explain it with classical ideas...)

Instead of splitting into 3's...

atoms exhibiting the Anomalous Zeeman Effect
split into quartets or sextuplets!

What one sees is:
Schrodinger model...but
expect triplets from the
transitions: one would
For 3 different $p \rightarrow 2$

Resolution could only see 3, not 4 lines
originally the "Sodium Doublet," as
say, in Sodium...the first one was called
