

The Experimental Basis of Quantum Theory

Thornton and Rex, Ch. 3

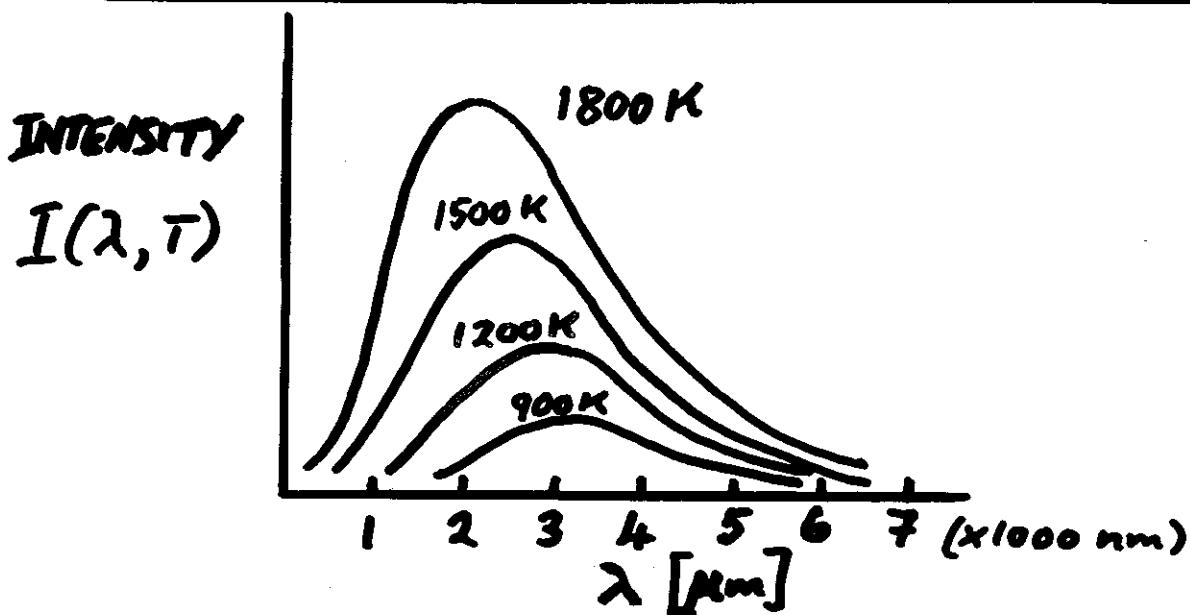

Blackbody Radiation

As an object gets hot, it radiates energy.

How does the radiation depend on temperature?

What is the distribution among frequencies (or wavelengths)?

BLACKBODY RADIATION

- MAXIMUM OF THE DISTRIBUTION SHIFTS TO SMALLER WAVELENGTHS AS THE TEMPERATURE INCREASES :-

$$\lambda_{\max} \cdot T = 2.898 \times 10^{-3} \text{ m.K}$$

WIEN'S
DISPLACEMENT
LAW

$$• \text{TOTAL POWER } = R(T) = \int_0^{\infty} I(\lambda, T) d\lambda = \epsilon \sigma T^4$$

STEFAN -
BOLTZMANN
LAW

WITH ϵ = EMISSIVITY AND σ = S-B CONSTANT
 $= 5.67 \times 10^{-8} \frac{\text{W}}{\text{m}^2 \text{K}^4}$

Max Planck, prof. at University of Berlin, attempted an explanation in 1900, adding one new and strange assumption:

Each oscillation mode can not absorb just any amount of energy. Each mode can only absorb energy in packets of fixed size.

It described the data perfectly!

The size of each energy packet (now termed a quantum) is proportional to the frequency of the mode:

$$E = h \nu$$

The proportionality factor (Planck's constant) is

$$h = 6.63 \times 10^{-34} \text{ J s.}$$

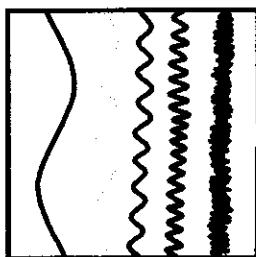

The above formula was first presented at a meeting of the German Physical Society on Dec. 14, 1900.

The birthday of Quantum Physics!

Max Planck derived:

$$I(\lambda, T) = \frac{2\pi c^2 h}{\lambda^5} \frac{1}{e^{hc/\lambda kT} - 1}$$

Planck's Radiation Law

Important new assumption:

The energy in each frequency mode ν can only come in integer multiples of some fundamental unit (quanta):

$$E = h \nu$$

with

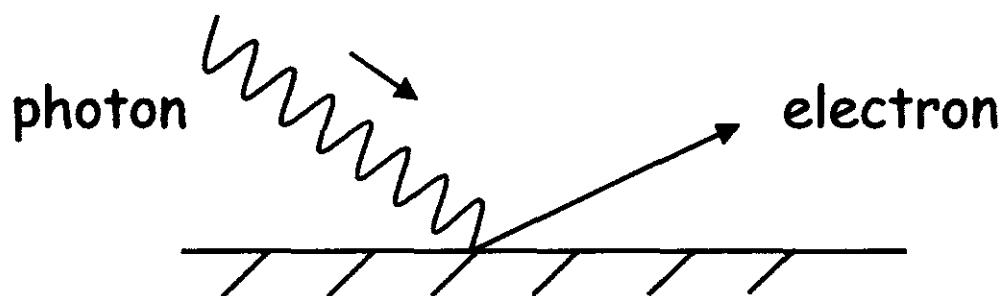

$$\begin{aligned} h &= 6.6261 \times 10^{-34} \text{ J} \cdot \text{s} \\ &= 4.1357 \times 10^{-15} \text{ eV} \cdot \text{s} \end{aligned}$$

The S-B law and Wien's law both follow from Planck's formula.

The Photoelectric Effect

1887 - Hertz:

Visible or UV light on metal surface may release electrons

Classical theory says energy of electrons should increase with intensity of light.

However, this was not the case.

Experiments (Lenard) showed:

- 1) KE of photoelectrons depends only on ν (frequency) of light, independent of I (its intensity).
- 2) # of photoelectrons is proportional to I
- 3) For a given metal, there is a minimum ν , below which no photoelectrons are emitted.
- 4) The photoelectrons are emitted instantaneously, independent of I.

Classical theory could not explain these observations.

1905 - Einstein explained:

Electromagnetic radiation transferred in discrete bundles of energy ("photons").
The energy of each photon is

$$E = h \nu$$

The KE of an emitted photoelectron is

$$KE = h \nu - \phi$$

- $h\nu$ is Energy of the incident photon
- ϕ is the binding energy of electron to the metal surface (the work function).

The KE of the electrons can be measured by applying a positive voltage to the surface and noting when the photoelectric current stops. This voltage is called the stopping potential.

3.34 WHAT IS THE THRESHOLD FREQUENCY FOR PHOTOELECTRONS FROM LITHIUM ($\phi = 2.9 \text{ eV}$)?

$$E_{\text{PHOTON}} = KE_{\text{ELECTRONS}} + \phi$$

$$\text{AT THRESHOLD } KE_{\text{ELECTRONS}} = 0$$

$$\therefore E_{\text{PHOTON}} = \phi = 2.9 \text{ eV}$$

$$\therefore h\nu = 2.9 \text{ eV}$$

$$\therefore \nu = \frac{2.9}{h} = \frac{2.9}{4.14 \times 10^{-15}}$$

$$\therefore \nu = 7.00 \times 10^{14} \text{ Hz}$$

$$(\lambda = c/\nu = 429 \text{ nm})$$

WHAT IS THE STOPPING POTENTIAL IF $\lambda = 400 \text{ nm}$?

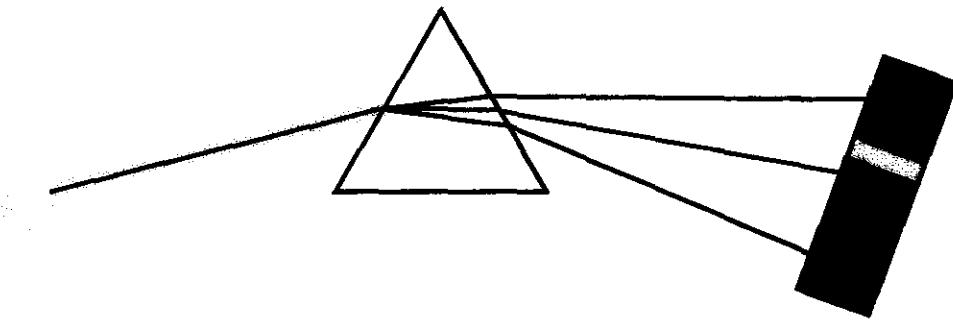

$$E_{\text{PHOTON}} = \frac{1243}{400} = 3.11 \text{ eV}$$

$$KE_{\text{ELECTRONS}} = E_{\text{PHOTON}} - \phi$$

$$= 3.11 - 2.9 = 0.21 \text{ eV}$$

SO ELECTRONS WILL BE STOPPED WITH A POTENTIAL OF 0.21 V.

Spectral Lines

- 1814-1824: Von Fraunhofer discovered absorption lines in sun.
- 1850's: Kirchhoff discovered characteristic emission lines of elements
- 1859: Kirchoff and Bunsen discovered new elements, Cesium and Rubidium, by first observing their spectral lines.

- 1885: Balmer found a formula for the wavelengths of the spectral lines in Hydrogen:

$$\frac{1}{\lambda} = R_H \left(\frac{1}{4} - \frac{1}{n^2} \right)$$

where $n=3,4,5,\dots$

The constant R_H is Rydberg's constant:

$$R_H = 1.096776 \times 10^7 \text{ m}^{-1}$$

- 1890: Rydberg found a more general formula for the spectral lines of Hydrogen:

$$\frac{1}{\lambda} = R_H \left(\frac{1}{m^2} - \frac{1}{n^2} \right)$$

where both n and m are integers with $n > m$.

Visible light is in the approximate range
 $400 \text{ nm} < \lambda < 700 \text{ nm}$

$m=1$: Lyman series \Rightarrow Ultraviolet (UV)
 $(\lambda < 122 \text{ nm})$

$m=2$: Balmer series

$n=3$: $\lambda = 657 \text{ nm}$

$n=4$: $\lambda = 486 \text{ nm}$

$n=5$: $\lambda = 434 \text{ nm}$

$n=6$: $\lambda = 410 \text{ nm}$

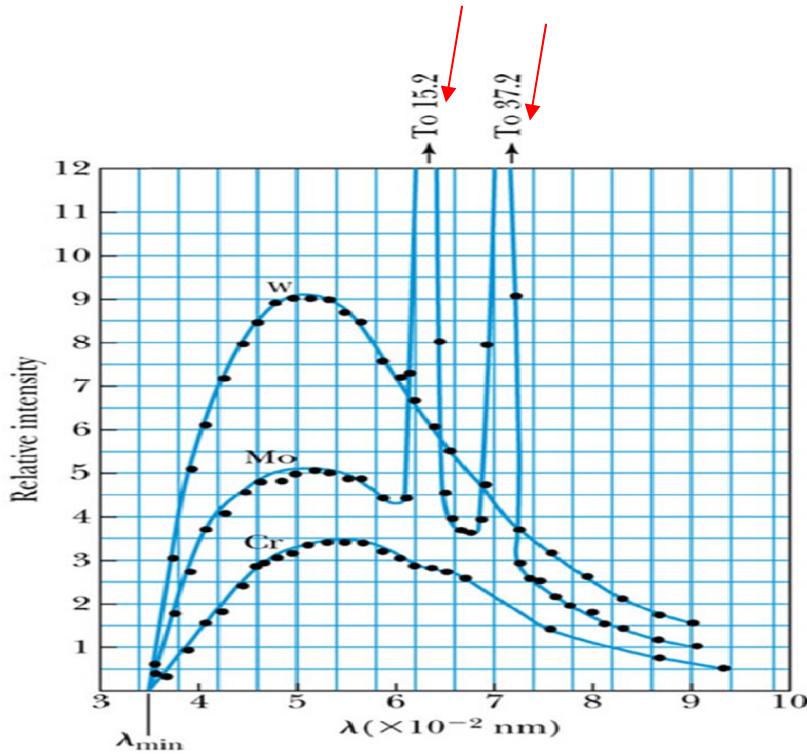

$n>7$: Ultraviolet ($\lambda < 397.1 \text{ nm}$)

$m=3$: Paschen series \Rightarrow Infrared (IR)
 $(\lambda > 820 \text{ nm})$

X Ray Spectra

Electrons bombarding a high-Z target

Incident electron KE: $K_0 = eV_0$

© 2006 Brooks/Cole - Thomson

Wavelength distribution of X-Rays

"Lines": knock atomic e's out of metal anode
(see spectral lines in a few slides)

Smooth continuum:

Deceleration of incident e's in anode radiate X rays

Distribution of energies: bremsstrahlung

$$\text{Xrays: } E = h\nu = hc/\lambda$$

For a given incident KE, largest loss = smallest λ

$$\lambda_{\min} = hc/K_0 \quad \text{or} \quad K_0 = 1240/\lambda_{\min} (\text{eV nm})$$

Example: cutoff wavelength of .035 nm corresponds to acceleration voltage V of

$$K_0 = eV = 1240 \text{ eV nm} / .035 \text{ nm}, \text{ so } V = 3550 \text{ Volts}.$$

Note: hc is very flexible:

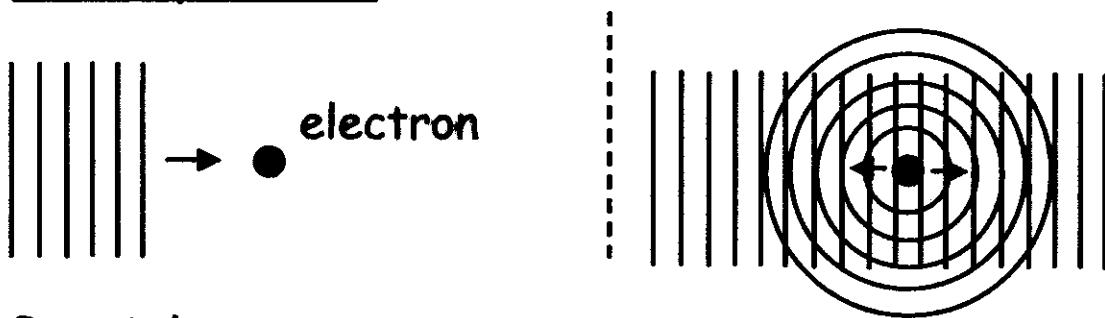

coordinated change of units in energy and wavelength

$$\begin{aligned} hc &= 1240 \text{ eV nm nano} \\ &= 1240 \text{ keV pm pico} \\ &= 1240 \text{ MeV fm femto} \end{aligned}$$

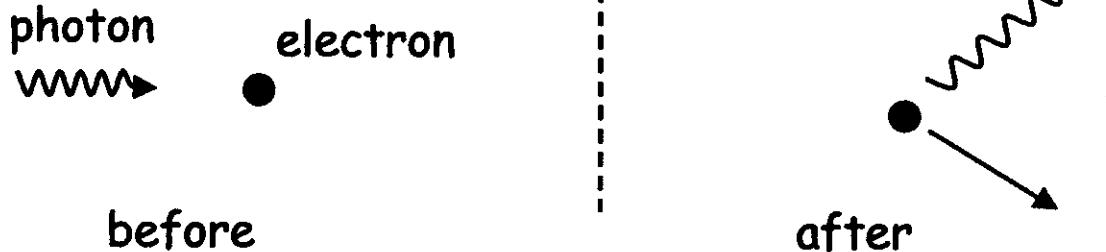

Compton Scattering

- Photoelectric effect, X-ray spectra suggest that photons, as well as being electromagnetic waves, also act like particles.
- This effect is even more pronounced in scattering of X-rays off electrons.

Wave picture:

Particle picture:

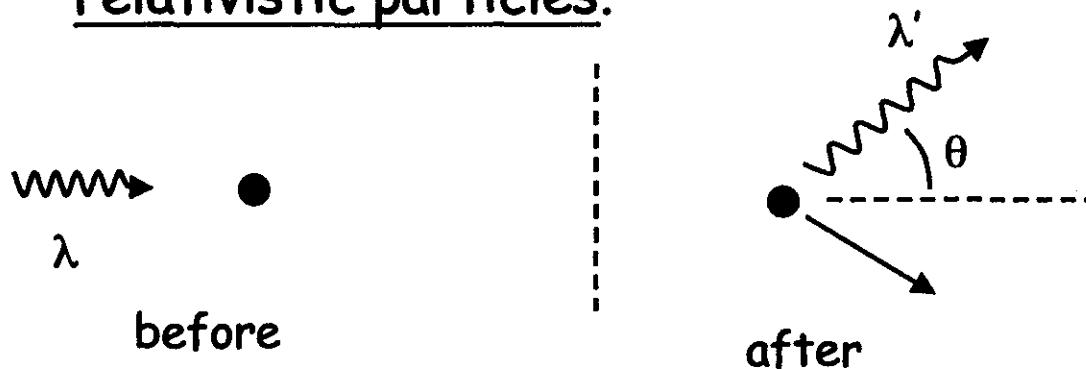

- 1923 -
Experiments by Arthur Compton.
He observed:

Some component of the scattered wave (especially at backward-scattering angles) has a longer wavelength than the incoming wave.

$$\lambda' > \lambda$$

- This could not be understood purely in terms of light as a wave.
- Compton showed that it was understandable as a scattering of relativistic particles.

The formula for the shift in wavelength is

$$\Delta\lambda = \lambda' - \lambda = \frac{h}{mc} (1 - \cos \theta)$$

with

λ' the scattered wavelength

λ the incoming wavelength

θ the scattering angle

m the electron mass

The combination

$$h/(mc) = 2.43 \times 10^{-12} \text{ m} = 2.43 \times 10^{-3} \text{ nm}$$

is called the Compton wavelength of the electron.

Compton Effect ($c=1$)

$$E \text{ cons: } p + m = p' + \sqrt{q^2 + m^2} \quad (1)$$

$$P_x \text{ cons: } p = p' \cos\theta + q \cos\varphi \quad (2)$$

$$P_y \text{ cons: } 0 = p' \sin\theta + q \sin\varphi \quad (3)$$

Eliminate φ : add squares of (2), (3)

$$(p - p' \cos\theta)^2 + (p' \sin\theta)^2 = q^2 = p^2 + p'^2 - 2pp' \cos\theta$$

Or ($\Delta p = p - p'$)

$$q^2 = (\Delta p)^2 + 2pp' (1 - \cos\theta) \quad (4)$$

Eliminate q with square of (1):

$$(\Delta p)^2 + 2m \Delta p + m^2 = q^2 + m^2 ; \text{ combine with (4)}$$

$$2m \Delta p = 2pp' (1 - \cos\theta) \quad (5)$$

$$1/p' - 1/p = (1 - \cos\theta)/m \quad (6)$$

Restore c 's: $1/p'c - 1/pc = (1 - \cos\theta)/mc^2$

Use $pc = hc/\lambda$ (only NOW use λ at all!)

$$1/\lambda' - 1/\lambda = (h/mc) (1 - \cos\theta)$$

4 vector rules (“not on the exam”—but slick!)

To denote 4-vector I use P (caps);

personally, I use \underline{p} (script)

$P = (e, \underline{p})$ 2nd slot a vector (underscore or arrow);

\underline{p} is vector or p magnitude depending on context

$P \cdot P' = E E' - (\underline{p} \cdot \underline{p}')$ mixed-sign dot product (invariant!)

$P^2 = e^2 - p^2 = M^2$ special case of dot product

compare: $(\Delta ct)^2 - (\Delta x)^2$

Compton Effect with 4-vector conservation:

$P = (p, \underline{p})$ and $m = (m, \underline{0})$ to P' , Q

$P + (m, \underline{0}) = P' + Q$ so, using $\Delta P = P - P'$

$$Q = \Delta P + m \quad (1)$$

Squaring:

$$Q^2 = m^2 = \Delta P^2 + 2m \cdot \Delta P + m^2$$

For a photon, $P = (p, \underline{p})$ and $P^2 = 0$

$$0 = 0 + 0 - 2\underline{p} \cdot \underline{p}' + 2m \Delta p \quad \text{which is again (5)}$$

COM frame M^2 for fixed target: (e, \underline{p}) and $(m, \underline{0})$

$$M^2 = (P+m)^2 = P^2 + m^2 + 2P \cdot m = 2m^2 + 2em = 2m(e+m)$$

$$M = \sqrt{2m(e+m)} \sim \sqrt{2mk}$$

COM frame M^2 for collider: (e, \underline{p}) and $(e, -\underline{p})$

$$\begin{aligned} M^2(cm) &= (P+P')^2 = 2m^2 + 2P \cdot P' \\ &= 2m^2 + 2(e^2 - \underline{p} \cdot (-\underline{p})) = 4e^2 \end{aligned}$$

$$M = 2e = 2(k+m) \sim 2k$$
