(Received 12 December 2012; published 24 June 2013)

We show that the rate of switching between the vibrational states of a modulated nonlinear oscillator is characterized by a quantum critical temperature \( T_c \) \( \propto \hbar^2 \). Above \( T_c \) there emerges a quantum crossover region where the switching rate displays a steep and characteristic temperature dependence, followed by a qualitatively different temperature dependence for higher \( T \). In contrast to the crossover between tunneling and thermal activation in equilibrium systems, here the crossover occurs between different regimes of switching activated by quantum fluctuations. The results go beyond the standard real-time instanton technique of the large-deviation theory.

I. INTRODUCTION

A modulated nonlinear oscillator models many well-controlled systems currently studied in cavity and circuit quantum electrodynamics, nanomechanics, and other areas [1]. This makes the oscillator advantageous for exploring quantum physics far from thermal equilibrium. Of fairly general interest in this respect are large rare quantum fluctuations that lead to switching between coexisting stable vibrational states (SVSs) and the occurrence of switching mechanisms that have no analog in equilibrium systems. The switching is important also for applications in quantum information [2–9]. For a characteristic system frequency [13,14], transitions over an effective barrier due to diffusion over oscillator eigenstates. It recalls thermal activation [12], except that the diffusion is due to quantum fluctuations that come along with the oscillator relaxation, with Planck playing the role of temperature in thermal activation. Quantum activation was first seen in the experiment reported in [2].

A well-known effect in switching of thermal equilibrium systems is the crossover from quantum tunneling to overbarrier transitions, which occurs for \( k_B T = \hbar \omega_{cb} \), where \( \omega_{cb} \) is a characteristic system frequency [13,14]. In contrast, and surprisingly, the switching rates of a modulated oscillator \( W_{sw} \) calculated in the WKB-type approximation for \( T = 0 \) [15] and \( T > 0 \) can differ exponentially strongly even where in the \( T > 0 \) region the appropriately scaled ratio \( T/\hbar \to 0 \) [10,11]. Both for \( T = 0 \) and \( T > 0 \) switching occurs via transitions over an effective barrier rather than tunneling, but for \( T > 0 \) the system lacks detailed balance.

In this paper we study the low-temperature behavior of the oscillator switching rate \( W_{sw} \) and the crossover between the switching with and without detailed balance. The crossover has pronounced characteristic features accessible to direct experimental observation with the currently available systems. The conventional WKB-type approximation of the theory of rare events, the real-time instanton technique [16,17], does not apply in the crossover region, since the tail of the probability distribution has different decay lengths on the opposite sides of this region (both of them temperature independent). Our approach overcomes this problem. It bears also on rare events in chemical kinetics and population dynamics, where similar crossovers may occur [18].

Quantum states of a periodically modulated oscillator are the quasienergy (Floquet) states [19]. Coupling of the oscillator to a thermal reservoir leads to transitions between them and thus to oscillator relaxation toward SVSs. In a simple picture relaxation comes from emission of excitations of the bath, for example, photons with energy \( \approx \hbar \omega_0 \), where \( \omega_0 \) is the oscillator eigenfrequency. The relaxation is accompanied by noise, because photons are emitted at random. The noise leads to oscillator fluctuations and diffusion away from SVSs. For \( T > 0 \), along with the noise from photon emission, there is noise from photon absorption. Its intensity is proportional to the oscillator Planck number \( \hbar = \exp(\hbar \omega_0/k_B T) - 1 \)^{-1}.

An insight into the oscillator dynamics can be gained from Fig. 1. It shows the scaled Hamiltonian \( g(Q,P) \) of a nonlinear oscillator modulated at frequency \( \omega_F \approx \omega_0 \). It is obtained in the rotating-wave approximation (RWA) from the full Hamiltonian \( H_0 = \frac{1}{2} p^2 + \frac{1}{2} \omega_0^2 q^2 + \frac{1}{2} \gamma q^4 - A q \cos(\omega_F t) \) by changing to the rotating frame using the transformation \( U(t) = \exp(-i\omega_F a^\dagger a t) \). Here \( (q,p) \) and \( (Q,P) \) are the oscillator coordinates and momenta in the laboratory and rotating frame, respectively, and \( a^\dagger \) and \( a \) are the raising and lowering operators (cf. [3,4,10]),

\[
g(Q,P) = \frac{1}{2}(Q^2 + P^2 - 1)^2 - \beta^{3/2} Q, \quad [Q,P] = i\lambda; \quad \beta = 3|\gamma|A^2/32\omega_0^4|\omega_F - \omega_0|^3 \quad \text{is the scaled field intensity} \quad \text{and} \quad \lambda = 3\hbar \gamma/8\omega_0^2(\omega_F - \omega_0) \quad \text{is the scaled Planck constant.}
\]

The extrema of \( g(Q,P) \) correspond to the SVSs in the weak-damping limit. Quasienergy states localized about an extremum are analogous to intrawell quantum states of a particle in a static potential. We count them off from the corresponding extremum.

II. BALANCE EQUATION AND THE EIKONAL APPROXIMATION

For weak damping, the state populations $\rho_n$ are given by a balance equation. In slow time $\tau = |\omega_F - \omega_0| t$

$$\rho_n = d\rho_n/d\tau = \sum_m (W_{mn}\rho_m - W_{nm}\rho_n). \quad (2)$$

We are interested in solving this equation in the WKB limit $\lambda \ll 1$ where the number of localized states $M \sim 1/\lambda \ll 1/\hbar$ is large. In this limit Eq. (2) is similar to the balance equations studied in chemical kinetics and population dynamics, with $M$ playing the role of the number of molecules or the total population [17]. On times large compared to the oscillator relaxation time but small compared to the reciprocal switching rate, the distribution $\rho_n$ becomes quasi-stationary. It can be sought in the eikonal form

$$\rho_n = \exp(-R_n/\lambda), \quad R_n \equiv R(g_n); \quad \lambda \ll 1. \quad (3)$$

Here $g_n$ is the eigenvalue of $g$ in quantum state $n$, i.e., the scaled quasienergy of state $n$. The dimensionless rate of switching from the initially occupied SVS $W_{sw}$ is determined by the population of states with quasienergies $g_n$ close to the saddle-point quasienergy $g_s$ in Fig. 1 [12],

$$W_{sw} \sim \kappa \exp(-R_A/\lambda), \quad R_A = R(g_s). \quad (4)$$

where $\kappa$ is the oscillator decay rate scaled by $|\omega_F - \omega_0|$.

The central approximation of the real-time instanton approach is that in Eq. (3) $R_n$ smoothly varies with $n$, so that $|R_{n+m} - R_n| \approx m|\partial_n R_n|$ for $|m| \ll 1/\lambda$, with $|\partial_n R_n| \ll \lambda \ll 1$. This approximation can break down in a nontrivial way, and in what follows we show how to find $\rho_n$ where this happens.

The dimensionless transition rates $W_{mn}$ for $|m-n| \ll 1/\lambda$ for a modulated oscillator were calculated earlier [10] and are given for completeness in Appendix A. Oscillator relaxation corresponds to transitions toward the SVS and is described by rates $W_{sw}$, with $m > n$. Transitions with $m < n$ lead to diffusion away from the SVS.

The rates $W_{mn} = W^{(e)}_{mn} + W^{(abs)}_{mn}$ have two terms, which come from emission and absorption of bath excitations, respectively: $W^{(abs)} \propto \bar{n}$. Both terms exponentially decay with increasing $|n-m|$. However, the decay of $W^{(abs)}$ with increasing $n - m > 0$ is slower, as can be seen from Eqs. (A2) and (A3). It is this difference that is at the root of the discussed behavior.

The ratio of the emission-induced rates is

$$W^{(e)}_{n\rightarrow n+k}/W^{(e)}_{n\rightarrow n-k} = \exp(-k/\xi_n), \quad (\xi_n > 0) \quad (5)$$

for $|k| \ll 1/\lambda$. The decay length $\xi_n \equiv \xi(g_n)$ smoothly varies with $n$. It is expressed in terms of the parameters of the classical orbits $Q(\tau; g)$ of a system with Hamiltonian $g(Q, P)$: $\xi(g) = \{2\nu g |\Im[r^{(e)}_p(g) - 2\tau_x(g)]|^{-1}\}$. Here, $\nu g$ is the vibration frequency of the system, $\tau_x(g)$ is the time it takes for $Q$ to go to infinity, and $r^{(e)}_p(g)$ is the complex period [the orbits $Q(\tau; g)$ are double periodic; the real period is $2\pi/\nu g$).

From Eqs. (2) and (5), for $T = 0$ we obtain for the quasistationary distribution $\rho_n(0)$ and the eikonal $R_n(0)$

$$\rho_{n\rightarrow n+k}/\rho_{n\rightarrow n-k} = \exp(-k/\xi_n), \quad \partial_n R_n(0) = \lambda/\xi_n. \quad (6)$$

The function $\partial_n R(0)(g_n) \equiv \partial_n R_n(0)/\partial_n g_n$ is shown in Fig. 2. One can associate $\partial_n R(0)/\lambda$ with the effective reciprocal temperature of the quasienergy distribution; this temperature itself depends on the quasienergy, $\rho_n(0) \propto \exp(-\int_0^{\infty} d\bar{g} R(0)(\bar{g})/\lambda)$. The absorption-induced transitions between the oscillator states perturb the $T = 0$ distribution. Because of the comparatively slow decay of $W^{(abs)}$ with $n - m > m$, the major perturbation comes from the absorption-induced influx from more populated states, which are closer to the extremum of $g(Q, P)$. For a state $n$, from Eq. (2) this influx scaled by the $T = 0$ rate of leaving the state $W^{(e)}_n \rho_n (W^{(e)}_n = \sum_m W^{(e)}_{mn})$ is

$$\zeta_n = \sum_{m<n} W_{mn}/W^{(e)}_n, \quad W_{mn} = W^{(abs)}_{mn}/\rho_n. \quad (7)$$

To the leading order in $\bar{n}$, in Eq. (7) $\zeta_n \rightarrow \zeta_n(0), \quad W_{mn} \rightarrow W^{(0)}_{mn}$, where the zeroth-order scaled influx $W^{(0)}_{mn} = W^{(abs)}_{mn}/\rho_n(0)$. If the rates $W^{(abs)}_{n\rightarrow n-k}$ decay with increasing $k$ more slowly than $\exp(-k/\xi_n)$, the parameters $W^{(0)}_{n\rightarrow n-k}$ increase with increasing $k$. This leads to nonlocality: the relative influx (7) is dominated by remote states $m$ with $n - m \gg 1$. In contrast, because of the lack of detailed balance, the flux from a state $n$ is still dominated by emission-induced processes,
\[ \sum_{m} W_{mn} \approx W_n^{(e)}. \]

Therefore in the limit \( \lambda \to 0 \), where the number of localized states \( M \to \infty \), the perturbation theory diverges.

III. BEYOND THE CONVENTIONAL LARGE-DEVIATION THEORY

In what follows we solve the balance equation in the parameter range where the zeroth-order scaled influx \( W_{mn}^{(0)} \) increases with \( n - m \). Our method is fairly general and it shows how one can go beyond the conventional large-deviation theory when the perturbation is singular. For concreteness, we analyze the distribution about the small-amplitude SVS, i.e., about the local maximum of \( g(Q,P) \) in Fig. 1, which is of primary interest for the experiment; cf. [2,5]. Since importance of are \( n - m \sim 1/\lambda \gg 1 \), it is necessary first to find the transition rates \( W_{mn} \) for large \( n - m \), where they are exponentially small. This can be done in the WKB approximation by extending the conformal mapping technique [20]. The calculation gives both the exponent and the prefactor in \( W_{mn} \); see Appendix B.

The explicit expressions for \( \xi_n \) and \( W_{mn} \) show that

\[ W_{mn}^{(0)} \propto \tilde{n}^{1/2} \exp \left[ \frac{1}{\lambda} \int_{g_e}^{g_0} d f (g) \right] \]

[for states localized about the local maximum of \( g(Q,P) \), \( g_0 < g_m \), for \( n > m \)]. The function \( f(g) = 2 \text{Im}[\tau_{mn}^{(0)}(g) - 3 \tau_{2mn}(g)] \) monotonically decreases with increasing \( g \) and goes through 0 for \( g = g_e \); in our model \( g_e \) is 1/4 independent of the scaled field intensity \( \beta \) in Eq. (1). Therefore \( W_{mn}^{(0)} \) displays a sharp maximum as a function of \( m \) for \( g_m \) closest to \( g_e \). Calculating \( \sum_{m} W_{mn}^{(0)} \) by the steepest-descent method, we obtain from Eq. (7)

\[ \tau_n^{(0)} = C_n \tilde{n}^{3/2} \exp \left[ \frac{1}{\lambda} \int_{g_e}^{g_0} d f (g) \right] \];

(8)

where \( C_n \propto (g_e - g_m)^2 \) is independent of \( \lambda \) and \( T \) [see Eq. (C2)].

The condition \( \tau_n^{(0)} \sim 1 \) (more precisely, \( |\tau_n^{(0)} - 1| \) is minimal) defines the characteristic level number \( n_{xc} \) and quasiequilibrium \( g_n \equiv g_{n}(T) \) for given \( T \) as well as the characteristic temperature \( T_{xc}(g_n) \) for given \( g_n \), where the \( T = 0 \) expression for the distribution (6) ceases to apply.

To allow for the thermally induced modification of the probability distribution we seek it in the form (3) with \( R_n \approx R_n^{(0)} + \Delta_n \). This is not a perturbative solution; we do not assume that \( |\Delta_n| \) is small or smoothly varying with \( n \). As we will see, \( |\Delta_n| \) remains small in a part of the distribution and is large but smooth as a function of \( n \) in another part. In these parts \( R_n \) is thus smooth, too. It is of critical importance that the transition between the corresponding regions of \( n \) occurs in a narrow range, and in this range \( R_n \) steeply changes with \( n \), in contrast to the conventional assumption of the large-deviation theory.

For small \( \tilde{n} \) we need to consider the absorption-induced transitions to a given state \( n \) only from states \( m \) with \( m < n \). Then the balance equation in the quasistationary regime reads

\[ \sum_{m < n} \left( W_{mn}^{(e)}/W_{n}^{(e)} \right) e^{(\Delta_n - \Delta_m)/\lambda} = 1 = -\tau_n^{(0)}. \]

(9)

From Eq. (7), \( \tau_n^{(0)} = \sum_{m < n} W_{mn}^{(0)} \exp[(\Delta_n - \Delta_m)/\lambda]/W_{n}^{(e)}. \)

We start with the distribution for states \( n \) comparatively close to the extremum of \( g, n_{xc} \sim n \gg 1 \). For such \( n \) we expect the correction to \( \rho_n \) to be small. Respectively, in Eq. (9) we replace \( \tau_n \) with \( \tau_n^{(0)} \) and expand the left-hand side to first order in \( \Delta_n, \Delta_m \), which gives

\[ \Delta_n = -\lambda \tau_n^{(0)}/\rho_n. \]

(10)

The parameter \( a_n > 0 \) is given in Eq. (C3); \( a_n \sim 1 \) and is independent of \( \lambda \). From Eqs. (8) and (10), \( |\Delta_n| \) is exponentially small for large \( n_{xc} \ll n \) but increases with \( n \) exponentially fast.

For states with \( n > n_{xc} \), the absorption-induced influx into a state is no longer small and must be balanced by emission-induced transitions from the state, which means \( \tau_n \sim 1 \). It is convenient to split the sum over \( m \) in \( \tau_n \) in Eq. (7) into a sum from \( n - 1 \) to \( n_{xc} - \delta n \) and a sum over \( m < n_{xc} - \delta n \), where \( 1 \ll \delta n \ll 1/\lambda \). We denote these sums as \( \tau_n^{(0)} \) and \( \tau_n^{(0)'} \), respectively. In calculating \( \tau_n^{(0)'} \), in the sum over \( m \) one can approximate \( \rho_m \) by \( g_{m}^{(0)} \), since the correction \( \Delta_m \), Eq. (10), is exponentially small for \( n_{xc} - m \gg 1 \). Taking into account the exponential dependence of \( W_{mn}^{(0)} \) on \( m \) and \( n \), one can see that the leading contribution to \( \tau_n^{(0)'} \) comes from transitions from remote states with \( g_m \sim g_e \).

\[ \tau_n^{(0)'} = \frac{1}{\rho_n} \left( \sum_{m = n - \delta n}^{n_{xc} - \delta n} \left( W_{mn}^{(0)}/W_{n}^{(e)} \right) e^{(\Delta_n - \Delta_m)/\lambda} \right) \]

(11)

We first consider the temperature range where \( \tilde{n} \ll \lambda^3 \), which includes the limit \( T \to 0 \). Here, as seen from Eq. (12), below, we can disregard the term \( \tau_n^{(0)} \) in \( \tau_n \). Then from Eqs. (8), (9), and (11) and from the condition \( \tau_n^{(0)} \sim 1 \) we obtain

\[ \Delta_n \approx -\int_{g_{n-\delta n}}^{g_{n+\delta n}} d g f (g), \quad n - n_{xc} \gg 1. \]

(12)

In contrast to the exponentially steep \( n \) dependence of \( \Delta_n \) for \( n < n_{xc} \) in Eq. (10), \( \Delta_n \) of the form (12) smoothly depends on \( n \). Corrections to Eq. (12) come from the approximations made in Eqs. (8) and (11) and the dependence on \( n \) of the left-hand side of Eq. (9). They are \( \sim \lambda \). From the expression for \( W_{mn}^{(0)} \) and Eq. (11), for \( \Delta_n \) of the form (12) \( \tau_n^{(0)} \ll \tilde{n}^{3/2} \ll \lambda \).

For \( \lambda^{3/2} \gg \tilde{n} \gg \lambda^3 \), on the other hand, transitions to states with \( n - n_{xc} \gg \tilde{n}^{1/3} \) are balanced locally and \( \tau_n^{(0)} \gg \tau_n^{(0)'} \). The analysis of this case is similar, and the leading term in \( \Delta_n \) is still given by Eq. (12), but \( \Delta_n \) has an important correction \( \sim \tilde{n}^{1/3} \); see Appendix C.

The boundary layer between the solutions (10) and (12) is centered at \( n_{xc} \) and has width \( |n - n_{xc}| \sim 1 \). Inside the layer \( |\Delta_n| \sim \lambda \) is given by the full equation (9).

Equations (6) and (12) give the eikonal of the probability distribution in the explicit form, with \( R_n \approx R_n^{(0)} + \Delta_n \gg 1 \) and \( R_n \equiv R_n^{(0)} + \Delta_n \), where \( n_{xc} \) is the level (12) for \( n - n_{xc} \gg 1 \). For \( |n - n_{xc}| \gg 1 \) the derivative \( \partial_n R_n \) is smooth. In the region \( |n - n_{xc}| \sim 1 \) it displays a kink. It sharply drops with increasing \( n \) by \( \sim \tilde{n}^{3/2} \) for \( n_{xc} - n \gg 1 \) to \( \lambda^{3/2} \tilde{n}^{-1} - v_n f (g_n) \) for \( n - n_{xc} \gg 1 \). The kink is seen in the numerical data in Fig. 2(a).
IV. CONCLUSIONS

The kink of the exponent of the probability distribution, i.e., of $\ln \rho_n/\rho_{n-1}$, is a singular modification of the distribution compared to the prediction of the conventional real-time instanton approach. Remarkably, it emerges where the perturbation formally remains small compared to the WKB parameter. In the present case, the corresponding condition is $\bar{n} \ll \lambda \propto \hbar$. One might hypothesize that this is a generic feature of the breakdown of the real-time instanton approach.

In the underdamped modulated oscillator, with increasing $T$ the kink emerges at the critical temperature $T_{c 1} = T_c(g_n)$. This is because $\zeta_n^{(0)}$ as given by Eq. (8) monotonically increases with $n$, and therefore the condition $\zeta_n^{(0)} \approx 1$ is first met with increasing $T$ at the saddle point, $g_n \approx g_{n*}$, where $n$ is maximal. From Eq. (8)

$$T_{c 1} = \hbar \omega_0 \lambda \int_{g_{n*}}^{g_{n*}} dg f(g) \propto \hbar^2.$$

For $T < T_{c 1}$ the distribution $\rho_n$ and the switching rate $W_{sw}$ are well described by the $T = 0$ expressions.

For $T > T_{c 1}$, the kink of $\delta_n R_n$ moves with the increasing $T$ from $g_n \approx g_{n*}$ to $g_n \approx g_{n*}$. From Eq. (8), it approaches $g_n$ and disappears for $\bar{n} \sim \lambda^{1/2}$ or $T \sim T_{c 2} = \hbar \omega_0/k_B \ln \lambda$, still deep in the quantum domain, $T_{c 2} \propto \hbar^2 / |\ln \lambda|$. For $T_{c 1} < T < T_{c 2}$ the effective switching activation energy $R_{A} \approx |\ln W_{sw}|$ is

$$R_{A} \approx \int_{g_{n*}}^{g_{n*}} dg \delta_n R^{(0)}(g) + \int_{g_{n*}}^{g_{n*}} dg \delta_n R^{(T)}(g) \quad (13)$$

$[g_{n*}]$ is the quasienergy of the occupied SVS; from Eq. (12), $\delta_n R^{(T)} = \partial_n R^{(0)} + f(g)$). It depends on $T$ through $g_n$ and, for $\bar{n} \gg \lambda^{3}$, through $R^{(T)}$.

From Eq. (8),

$$d \ln W_{sw}/dT^{-1} \approx - (\hbar \omega_0/k_B) \quad \text{for} \quad \bar{n} \ll \lambda^{3},$$

i.e., the slope of the logarithm of the switching rate displays a plateau with height independent of the modulation. This unexpected behavior emerges because remote quasistationary states are populated nonlocally, through the influx directly from the vicinity of the SVS with rates $\propto \lambda$. Our analysis refers to the states localized about the local maximum of $g(Q, P)$, and we count the states off from this maximum.

Intermediate transitions result from the oscillator coupling to a thermal reservoir. For a weak coupling, the dynamics of the resonantly modulated oscillator can often be described in slow time $\tau = |\omega_F - \omega_0| t$ by a Markov master equation for the oscillator density matrix $\rho$. To the lowest order in the coupling, the coupling-induced term in this equation has a familiar form [21],

$$(d \rho/d\tau)_{cpl} = - \kappa (\bar{n} + 1)(a^\dagger a \rho - 2a^* a \rho + a a^\dagger \rho)$$

We assumed here that the coupling is linear in the oscillator raising and lowering operators $a^\dagger$ and $a$. The coupling-induced renormalization of the oscillator parameters has been incorporated into their values; $\kappa$ is the scaled oscillator decay rate. It has not been assumed that the coupling leads to Ohmic dissipation. The approximation involved relies on the smallness of corrections $\sim (\kappa/k^{(0)} \Delta \omega, \kappa \Delta \omega^{(0)}$ and similar corrections for the polaronic frequency shift. Here, $\Delta \omega$ includes the frequency detuning of the driving field $\omega_F - \omega_0$ and the nonlinear shift of the eigenfrequency with vibration amplitude, for typical amplitudes (for thermally excited vibrations, this shift depends on temperature, but this case is not of interest for this paper). An extra confirmation of the applicability of Eq. (A1) is that, in the absence of modulation, its results coincide [22] with the results obtained with the double-time Green’s function technique [23], which apply for arbitrary temperature.

From Eq. (A1), the scaled rates of transitions between the eigenstates $\psi_m$ and $\psi_n$ due to emission and absorption of the switching rate, which lies between the critical temperatures $T_{c 1} \propto \hbar^2$ and $T_{c 2} \propto \hbar / |\ln \lambda|$. In this region the slope of the logarithm of the oscillator distribution over quasienergy states, which is the analog of the effective reciprocal temperature for this distribution, displays a kink. The slope changes from the $T = 0$ value, where the dissipation-induced interstate transitions are balanced within a few nearest states, to the value where long-range transitions are important. As a consequence, in the deeply quantum regime the temperature dependence of the oscillator switching rate mimics the activation law with the activation energy $\hbar \omega_0$ independent of the modulation strength. The results bear on the current experiments on nonlinear cavity modes and modulated Josephson junctions.

APPENDIX A: MATRIX ELEMENTS BETWEEN CLOSE QUASIENERGY STATES

For completeness, we first give the rates of transitions between close eigenstates of the oscillator Hamiltonian in the rotating frame $g(Q, -i\lambda \delta_Q)$, which is defined in Eq. (1) (see [10,11]). The function $g(Q, P)$ has the shape of a tilted Mexican hat; see Fig. 1. Our analysis refers to the states localized about the local maximum of $g(Q, P)$, and we count the states off from this maximum.

Intermediate transitions result from the oscillator coupling to a thermal reservoir. For a weak coupling, the dynamics of the resonantly modulated oscillator can often be described in slow time $\tau = |\omega_F - \omega_0| t$ by a Markov master equation for the oscillator density matrix $\rho$. To the lowest order in the coupling, the coupling-induced term in this equation has a familiar form [21],

$$\frac{d \rho}{d\tau} = -\kappa(\bar{n} + 1)(a^\dagger a \rho - 2a^* a \rho + a a^\dagger \rho)$$

We assumed here that the coupling is linear in the oscillator raising and lowering operators $a^\dagger$ and $a$. The coupling-induced renormalization of the oscillator parameters has been incorporated into their values; $\kappa$ is the scaled oscillator decay rate. It has not been assumed that the coupling leads to Ohmic dissipation. The approximation involved relies on the smallness of corrections $\sim (\kappa/k^{(0)} \Delta \omega, \kappa \Delta \omega^{(0)}$ and similar corrections for the polaronic frequency shift. Here, $\Delta \omega$ includes the frequency detuning of the driving field $\omega_F - \omega_0$ and the nonlinear shift of the eigenfrequency with vibration amplitude, for typical amplitudes (for thermally excited vibrations, this shift depends on temperature, but this case is not of interest for this paper). An extra confirmation of the applicability of Eq. (A1) is that, in the absence of modulation, its results coincide [22] with the results obtained with the double-time Green’s function technique [23], which apply for arbitrary temperature.

From Eq. (A1), the scaled rates of transitions between the eigenstates $\psi_m$ and $\psi_n$ due to emission and absorption of
excitations of the thermal reservoir are, respectively,
\[ W_{mn}^{(e)} = 2\kappa(n+1)\langle a_{mn}\rangle^2, \quad W_{mn}^{(abs)} = \frac{\tilde{a}}{\tilde{n}+1} W_{mn}^{(e)}. \]  \hfill (A2)

Here, \( a_{mn} \equiv \langle \psi_n | \psi_n \rangle = (2\Lambda)^{-1/2}(Q+iP)_{mn^*}. \)

If the dimensionless Planck constant \( \hbar \) for motion in the rotating frame is small, \( \lambda \ll 1 \), one can find \( a_{mn} \) using the WKB approximation for \( \psi_n(Q) \). A significant simplification comes from the fact that the classical trajectories \( Q(\tau;g) \) of the system with Hamiltonian \( g(Q,P) \) are described by the Jacobi elliptic functions; \( Q(\tau;g) \) is double periodic on the complex-\( \tau \) plane, with real period \( \tau_1^{(1)}(g) \) and complex period \( \tau_2^{(2)}(g) \) \cite{10}. For \( |m-n| \ll \lambda^{-1} \) the matrix element \( a_{mn} \) is given by the Fourier \( m-n \) component of the function \( a(\tau;g) = (2\Lambda)^{-1/2}Q(\tau;g) + iP(\tau;g) \) \cite{24}. In turn, this gives
\[ W_{n+\gamma k}^{(e)} = \frac{e^{\kappa(n+1)\gamma_\gamma} \exp[k_q \text{Im}(2\tau_0 - \tau_2^{(2)})]}{\sinh \left(ik_q \tau_2^{(2)}(g)/2 \right)^2}. \]  \hfill (A3)

Here, \( \tau_0 \equiv \tau_0^0(g_n) \) and \( \tau_2^{(2)} = \tau_2^{(2)}(g) \); \( \tau_0(g_n) \) is the pole of \( Q(\tau;g_n) \) closest to the real axis; \( v_n = \pi/\tau_2^{(2)}(g_n) \) is the dimensionless frequency of vibrations in the rotating frame with quasienergy \( g_n \). To the leading order in \( \lambda \), we have \( W_{n+\gamma k}^{(e)} = W_{n-k}^{(e)} \). Equation (A3) has to be modified for states very close to the extrema of \( g(Q,0) \); this modification is straightforward.

APPENDIX B: MATRIX ELEMENTS BETWEEN REMOTE QUASIENERGY STATES

In this Appendix we calculate in the WKB approximation the exponent and the prefactor of the matrix element \( a_{mn} \) for remote eigenstates \( \psi_\nu \) and \( \psi_\nu^* \). The approach we use is similar, but not identical, to that developed \cite{20} in the problem of a parametrically modulated oscillator. First, in the spirit of Ref. \cite{24}, we write
\[ a_{mn} = \text{Re} \int_{-\infty}^{\infty} dQ \psi_\nu Q^m \psi_\nu^* Q^n / \sqrt{2\lambda}. \]  \hfill (B1)

The function \( \psi_\nu^*(Q) \) is an eigenfunction of operator \( g(Q,P = 0) = -i\lambda \partial Q \) such that \( \text{Re} \{ \psi_\nu^*(Q) \} = \psi_\nu^*(Q) \) and that slightly above the real \( Q \) axis in the WKB approximation
\[ \psi_\nu^*(Q) \approx \left( -\frac{2\nu_n}{\pi \partial g_n} \right)^{1/2} \exp[i\lambda^{-1}S_n(Q) + i\pi/4]. \]  \hfill (B2)

Here, \( \partial g_n \) is \( \partial g \) calculated for the momentum \( P = P(Q,g_n) \). \( S_n(Q) \) is the mechanical action counted off from the right turning point \( Q(\tau_2^{(2)}(g_n); \text{Classical orbit}) \) that lies on the inner dome of the function \( g(Q,P) \) shown in Fig. 1, with \( g(Q,P) = g_n \). For the inner-dome orbits the momentum is
\[ P(Q,g) = \sqrt{1 - Q^2 - \sqrt{2\lambda}}, \]  \hfill (B3)

and \( S_n(Q) \) integrates over the real axis of \( Q \) from \(-\infty\) to \( Q_n(g_n) \). \( \tau_0 \) and \( \tau_{ext} \) are the times for reaching \( Q_n(g_n) \) and \( Q_{ext}(g_n) \). Above this interval on the complex-\( Q \) plane one of the terms in the cosine becomes exponentially small and should be disregarded in the WKB approximation \cite{24}, so that
\[ \psi_\nu(Q) \approx \left( -\frac{-1}{2\pi \partial Q g_n} \right)^{1/2} \exp[i\lambda^{-1}S_n(Q) - i\pi/4]. \]  \hfill (B4)

We will illustrate the calculation by considering the case \( g_n < \sqrt{\beta} \). For such \( g \), the orbits on the external part of \( g(Q,P) \) have the shape of a horseshoe. The function \( P(Q,g_n) \) as given by Eq. \( (B3) \) has a branching point \( Q_b = -g/\sqrt{\beta} \), which corresponds to the two utmost negative-\( g \) points of the horseshoe. It also has three zeros: \( Q_{ext}(g_n), Q_i(g_n), \) and \( Q_{ext}(g_n) \) on the real-\( Q \) axis, with \( Q_b < Q_{ext} < Q_i < Q_R \).

To calculate the integral in Eq. \( (B1) \) we change in the range \( Q > Q_{ext} \) to integration over a contour \( C \) shown in Fig. 3(a). On this contour, from Eqs. \( (B1), (B2), \) and \( (B4), \) and \( P(Q,g_n) \). We go around these points by lifting the integration contour above the real \( Q \) axis.

On the real-\( Q \) axis the WKB wave function \( \psi_\nu(Q) \) in Eq. \( (B1) \) is \( \psi_\nu(Q) \approx \cos[\lambda^{-1}S_n(Q) + \pi/4] \) for \( Q \) in the interval between the left and right turning points, \( Q_i(g_n) \) and \( Q_{ext}(g_n) \). Above this interval on the complex-\( Q \) plane one of the terms in the cosine becomes exponentially small and should be disregarded in the WKB approximation \cite{24}, so that
\[ \psi_\nu(Q) \approx \left( -\frac{-1}{2\pi \partial Q g_n} \right)^{1/2} \exp[i\lambda^{-1}S_n(Q) - i\pi/4]. \]  \hfill (B4)

FIG. 3. (Color online) (a) The contour of integration \( C \) for calculating the matrix element \( B6 \) in the WKB approximation and the auxiliary integration contours \( C' \) and \( C'' \). For \( g_n < \sqrt{\beta} \): \( Q_b \equiv Q_b(g_n) \) and \( Q_{ext} \equiv Q_{ext}(g_n) \) are the branching point and turning point of \( P(Q,g_n) \); see Eq. \( (B3) \). (b) Mapping of the \( Q \) plane (with a branch cut from \( Q_{ext} \) to \( \infty \), the black thin line in (a)) on the interior of a rectangle on the \( \tau \) plane for \( g_n < \sqrt{\beta} \) by the function \( Q(\tau;g) \) that describes the classical Hamiltonian trajectory with given \( g \), \( g_n < g < g_n^{ext} \). (c) The real and imaginary periods and the pole of \( Q(\tau;g) \), respectively. The solid \((C)\), dashed \((C')\), and dash-dotted \((C'')\) lines are the maps of the corresponding contours in (a). The solid arc in the lower left corner is the map of the real axis of \( Q \) from \(-\infty\) to \( Q_n(g_n) \). (d) Conformal mapping for \( g > \sqrt{\beta} \). The curved red line dividing the rectangle into two parts is the map of the real axis of \( Q \) from \(-\infty\) to \( Q_b \).
\[ a_+(Q) \approx a_+^{WKB}(Q) \]
\[ a_+^{WKB}(Q) = \pi^{-1}(v_n v_m / 2\kappa \partial_p g_n \partial_p g_m)^{1/2} \times [Q + i P(Q, g_n)] \exp \{i [S_n(Q) - S_m(Q)] / \lambda \}. \]  

(B5)

It is straightforward to show using the full expression for \( \psi_m(Q) \) that the real part of the exponent in the expression for \( a_+(Q) \) monotonically increases on the interval \((\infty, Q_{\text{ext}})\). Therefore, to logarithmic accuracy the upper bound of the contribution of the integral from \( \infty \) to \( Q_{\text{ext}} \) of \( a_+(Q) \) in Eq. (B1) is \( a_+(Q_{\text{ext}}) \sim a_+^{WKB}(Q_{\text{ext}}) \). Below we show that \( a_{mn} \) is exponentially larger than \( a_+^{WKB}(Q_{\text{ext}}) \). Then
\[ a_{mn} \approx \text{Re} \int_C dQ a_+^{WKB}(Q). \]  

(B6)

To evaluate the integral (B6), we analytically continue \( a_+^{WKB} \) to the plane with a branch cut on the semi-infinite interval \([Q, g_n(\infty), \infty)\). We then can change from integration along \( C \) to integration along the circle \( C_{\text{arc}} \) and contour \( C' \) shown in Fig. 3(a).

The function \( Q(\tau; g) \), which describes the classical trajectory for the Hamiltonian \( g(Q, P) \), provides conformal mapping of the \( Q \) plane (with a branch cut) onto a \( g \)-dependent region on the plane of complex time \( \tau \). We define \( \tau(Q, g) \) as the duration of classical motion from the turning point \( Q_{\text{left}}(g) \) to \( Q_{\text{right}} \). Then the region of the \( \tau \) plane that corresponds to the \( Q \) plane (with a branch cut) is a rectangle of a right angle shown in Fig. 3(b).

Since \( \tau(Q, g) = \partial S / \partial g \), the exponent in Eq. (B5) is
\[ \frac{i}{\lambda} \{ S_n(Q) - S_m(Q) \} = \frac{i}{\lambda} \int_{g_n}^{g_m} d\tau \tau(Q, g). \]  

(B7)

As seen in Fig. 3(b), for any \( g \) between \( g_n \) and \( g_m \), for any \( Q_{\text{arc}} \) on contour \( C_{\text{arc}} \) and any \( Q' \) on contour \( C' \), \( |\text{Im} \{ Q(\text{arc}, g) \} | < |\text{Im} \{ Q'(g, g) \} | \). Therefore, \( a_+^{WKB}(Q) \) is exponentially smaller on contour \( C' \) than on contour \( C_{\text{arc}} \), and the integral along \( C' \) can be disregarded. Moreover, \( a_+^{WKB}(Q_{\text{ext}}(g_m)) \ll a_{mn} \), as assumed in Eq. (B6).

The integral along \( C_{\text{arc}} \) can be evaluated using the asymptotic expressions \( P \approx -Q, \quad g_p \approx \beta \) \( 1/2 \) \( Q \) \( 1/2 \),
\[ i \frac{1}{\lambda} \{ S_n(Q) - S_m(Q) \} \approx \frac{i}{\lambda} \int_{g_n}^{g_m} d\tau \tau(g) + \frac{g_m - g_n}{\beta \lambda^{1/4} Q^{1/2}}. \]  

(B8)

With Eq. (B8), the integral (B6) is reduced to a simple residue, which gives
\[ a_{mn} \approx \left( \frac{2v_n v_m}{\beta \lambda^3} \right)^{1/2} (g_m - g_n) \exp \{i \lambda^{-1} \int_{g_n}^{g_m} d\tau \tau(g) \}. \]  

(B9)

For \( g_m > \sqrt{\beta} \), the small-momentum branch \( P(Q, g_m) \) (B3) has only two turning points. In the WKB approximation, \( a_+(Q) \approx a_+^{WKB}(Q) \) on contour \( C \) whose left end point is the branching point \( Q_{\text{left}}(g_n) \); see Fig. 3(c). The conformal mapping \( Q(\tau; g) \) has a different topology, which is shown in Fig. 3(d). Nonetheless, using the same arguments as before, we arrive at the same expression (B9) for the matrix elements \( a_{mn} \).

In Fig. 4 we compare the explicit analytical expression for the matrix elements \( a_{mn} \), which includes both the exponent and the prefactor, with the numerical calculations based on solving the Schrödinger equation \( \hat{g} \psi_n = g_n \psi_n \). The results are in excellent agreement.

APPENDIX C: THERMALLY INDUCED MODIFICATION OF THE T = 0 DISTRIBUTION

The explicit expression for the transition matrix elements \( B \) makes it possible to calculate the rate of absorption-induced transitions to a state \( n \) scaled by the rate of leaving this state \( g_n^{(0)} \), which is given by Eq. (7) with \( \rho_{mn}^{(0)} \), replaced by their \( T = 0 \) values \( \rho_{mn}^{(0)}(0) \). The most probable transitions are those from states \( m \) closer to the SVS, \( m < n \). From Eq. (B9), the term \( w_{mn}^{(0)} = W_{mn}^{(abs)}(0) / \rho_{mn}^{(0)}(0) \) in the expression for \( \chi_n^{(0)} \) for \( n - m \gg 1 \) is of the form
\[ w_{mn}^{(0)} \approx \tilde{n} \kappa n^{-3} C^{(w)}(g_m, g_n) \exp \left[ \kappa^{-1} \int_{g_n}^{g_m} \lambda^{-1} f(g)dg \right]. \]  

(C1)

with \( f(g) = 2 \text{Im} \{ \tau^2(g) - 3 \tau(g) \} \). As a function of \( m, w_{mn}^{(0)} \) is maximal for \( g_n \) closest to the quasienergy value \( g_e \), given by the condition \( f(g_e) = 0 \).

Calculating the sum of \( w_{mn}^{(0)} \) by the steepest-descent method, we obtain Eq. (8) for \( \chi_n^{(0)} \) with
\[ C_n = C^{(w)}(g_e, g_n) |2\kappa^2 \pi / \partial g f(g_e)|^{1/2} \lambda W_n^{(e)}. \]  

(C2)

The overall rate \( W_n^{(e)} \) of emission-induced transitions from state \( n \) for \( \tilde{n} \ll 1 \) can be found from Eq. (A3); using this equation we obtain \( C_n \approx C^{(w)}(g_e, g_n) 2\pi / \partial g f(g_e)|^{1/2} \).

The modification of the distribution \( \rho_{mn}^{(0)} \) by absorption-induced transitions becomes substantial when \( \tilde{n} \) is still exponentially small in \( \lambda, |\ln \tilde{n}| > \int_{g_e}^{g_m} f(g)dg / \lambda \). For small \( \tilde{n} \), the change \( \Delta_n \) of the eikonal, \( R_n = R_n^{(0)} + \Delta_n \), is described by Eq. (9). The solution of this equation for \( n_{\chi} - n \gg 1 \) is given by a simple perturbation theory and has the form of Eq. (10) of the main text with
\[ a_{n} \approx \sum_m \left( W_{mn}^{(e)} / W_n^{(e)} \right) \left[ 1 - \exp((m - n)u(g_n)f(g_n)) \right]. \]  

(C3)

Using the explicit form of \( W_n^{(e)} \), Eq. (A3), one can show that \( a_n > 0 \).
1. Temperature range \( \bar{n} \gg \lambda^3 \)

In this section we analyze the change \( \Delta_n \) of the eikonal of the probability distribution for \( 1 \gg \bar{n} \gg \lambda^3 \). As we will see, in contrast to the range \( \bar{n} \ll \lambda^3 \) discussed in the main text, for \( \bar{n} \gg \lambda^3 \) the dominating term in \( \kappa_\infty \) is \( \kappa_\infty' \). It describes the contribution from transitions from not too strongly separated states. From Eq. (11), the leading-order term in \( \Delta_n \) in the range \( n - n_\infty \gg \bar{n}^{-1/3} \) is still given by Eq. (12). However, when calculating \( \kappa_\infty' \) one should add a correction \(- (n - m) \epsilon_n \) to the leading term in \( (\Delta_n - \Delta_m)/\lambda \), with \(|\epsilon_n| \ll 1 \). This is reminiscent of the calculation of the correction to the eikonal for a parametric oscillator [11], which was done, however, away from the crossover region.

From Eq. (11) of the main text, the sum over \( m \) in \( \kappa_\infty' \) is a second derivative with respect to \( \epsilon_n \) of a geometric series, since the prefactor in \( u_{mn}^{(0)}(g_n, g_m) \propto (g_m - g_n)^2 \propto (n - m)^2 \) for \( |n - m| \ll 1/\lambda \); see Eq. (C1). Then

\[
\kappa_\infty' \approx (\bar{n} / \epsilon_n^3) C_{m}(g_n), \quad C_{m}(g_n) = 8V_n^4 \lambda \beta W_n^2. \tag{C4}
\]

The coefficient \( C_{m}(g) \) is independent of \( \lambda \), and is \( \sim 1 \) generally. Since \( \bar{n}_n \sim 1 \), from Eq. (C4) we have \( \epsilon_n \sim \bar{n}^{1/3} \), and

\[
\Delta_n \approx - \int_{g_n}^{g_m} d g f(g) - \bar{n}^{-1/3} \int_{g_n}^{g_m} d g v^{-1}(g) C_{m}(g), \quad n - n_\infty \gg 1. \tag{C5}
\]

The correction \( \propto \bar{n}^{1/3} \) in Eq. (C5) increases \(|\ln \rho_n| \) by a term \( \propto \bar{n}^{1/3} / \lambda \). Respectively, \( \kappa_\infty' \) as given by Eq. (11) becomes exponentially small, in agreement with the assumption that it could be disregarded. On the whole, as the ratio \( \bar{n}^{1/3} / \lambda \) changes from small to large, so also does the ratio \( \lambda / \kappa_\infty' \), starting from large \( n \).

From Eq. (C1) and from Eq. (8), for \( \bar{n} \) approaching \( \lambda^{3/2} \ll 1 \) the quasienergy \( g_\infty \) approaches \( g_m \). For \( \bar{n} \gg \lambda^{3/2} \), i.e., outside the crossover region, \( T > T_c \), the rates of transitions into all states with \( g_m < g_n \) are determined by absorption (thermal) processes. In this range \( \kappa_\infty = \kappa_\infty' \), and the eikonal \( R_n = R_{mn}^{(0)} + \Delta_n \) is determined by Eq. (C5). For \( \bar{n} \gg \lambda^3 \), the slope \( \partial |\ln W_n| / \partial T \propto (T_0 / k_B) \bar{n}^{1/3} / \lambda \) is much larger than in the region of the plateau, where it is equal to \( T_0 / k_B \).

---
